

Functional Programming Summer term 2023

Prof. Torsten Grust, Denis Hirn WSI — Database Systems Research Group

Assignment 5

Hand in this assignment until Friday, 8. June 2023, 10:00 at the latest.

Exam-style Exercises

Exercises marked with (E) are similar in style to those you will find in the exam. You can use these to hone your expectations and gauge your skills.

Running out of ideas?

Are you hitting a roadblock? Are some of the exercises unclear? Do you just need that one hint to get the ball rolling? Refer to the #forum channel on our Discord server and check the tag for this assignment—maybe you'll find just the help you need.

Task 1: Polynomials

What is a Number? Haskell's type system answers this question in a simple way. A number—i.e. an instance of type class Num—is anything that can be added, subtracted, multiplied, negated, and so on¹:

```
Prelude> :info Num
   class Num a where
     (+) :: a -> a -> a
4
     (-) :: a -> a -> a
     (*) :: a -> a -> a
6
     negate :: a -> a
     abs :: a -> a
8
     signum :: a -> a
9
     fromInteger :: Integer -> a
     {-# MINIMAL (+), (*), abs, signum, fromInteger, (negate | (-)) #-}
       -- Defined in 'GHC.Num'
12 [...]
```

Can a polynomial be such a number? Sure it can! Polynomials can be added, subtracted, and multiplied just like any other number. In this exercise, we will implement a representation for polynomials and make it an instance of Num. A polynomial is a sequence of terms. Each term has a coefficient and a degree. For example, the polynomial $x^2 + 5x + 3$ has three terms, one of degree 2 with coefficient 1, one of degree 1 with coefficient 5, and one of degree 0 with coefficient 3. Our representation of a polynomial in Haskell will be a list of coefficients, whose degrees correspond to their position (0,1,...) in the list:

```
1 data Poly a = P [a]
```

For example, the polynomial $x^2 + 5x + 3$ is represented as P [3,5,1]. The type of coefficients is polymorphic; in particular, polynomials over integers, floats, or booleans can be represented. However, most of the rest of this exercise only applies to polynomials with numeric coefficients. You may thus restrict the type to Num a => Poly a whenever necessary.

¹Note that division is not included. There is another type class, **Integral**, for that.

(a) (E) First, define a value x representing the polynomial f(x) = x.

```
1 | x :: Num a => Poly a
```

(b) (E) Write an instance of class Eq for polynomials with numeric coefficients.

Note

- It is *not* possible to simply compare the lists.
- · You don't have to implement function (/=) explicitly; it has a default implementation in terms of (==).

Examples:

(c) Polynomials, e.g. P [-3,2,0,-1], should be displayed in the following human-readable form:

```
1 (-x^3) + 2x + (-3)
```

- Terms are displayed as $c\mathbf{x}^{\bullet}e$ where c is the coefficient and e is the exponent. If e is 0, only c is displayed. If e is 1, the exponent is not displayed ($c\mathbf{x}$).
- Terms are separated by the + sign with a single space on each side.
- · Terms are listed in decreasing order of their degree.
- Terms with a coefficient 0 are not displayed, unless the whole polynomial equals 0.
- The coefficient 1 is not displayed, unless the degree is 0.
- Terms with negative coefficients (assume Ord a => Poly a to test for c < 0) can either be put in parentheses, or the leading operator + can be replaced by -. ² Both versions are fine. Example: $(-x^3) + 2x + (-3)$ or $-x^3 + 2x 3$.

Make Poly a an instance of class Show (implement function show :: Poly a -> String), following the specification above.

Examples:

```
1 show (P [1,0,0,2]) = "2x^3 + 1"
2 show (P [0,-1,2]) = "2x^2 + (-x)"
```

(d) The first function of a Num instance for polynomials (with numeric coefficients) is fromInteger :: Num a => Integer -> Poly a. An integer c is a polynomial of degree 0 with coefficient c. Remember that you have to convert the Integer to a value of type Num a => a before you can use it as coefficient.

Begin with an instance declaration for Num a => Num (Poly a) and define fromInteger. The declaration is to be completed with all other necessary function definitions in the following.

(e) (E) Addition on polynomials is fairly simple. All you have to do is to add the coefficients pairwise for each term of the same degree in the two polynomials. For example $(x^2 + 5) + (2x^2 + x + 1) = 3x^2 + x + 6$.

Write a function plusP which adds one polynomial to a second:

```
1 | plusP :: Num a => Poly a -> Poly a -> Poly a
```

Note

The type signature for <code>plusP</code> has the constraint that <code>a</code> has a <code>Num</code> instance. Because of that you can use all of the usual <code>Num</code> functions (i.e. (+)) on the coefficients of your polynomials.

Complete the definition of (+) in your instance using plusP. Examples:

```
1 | P [5,0,1] + P [1,1,2] = P [6,1,3]
2 | P [1,0,1] + P [1,1] = P [2,1,1]
```

²If there is no leading operator a simple an unary leading – without parentheses is fine, too.

(f) Multiplying two polynomials requires each term in the first polynomial to be multiplied by each term in the second polynomial. Implement a function

```
1 | timesP :: Num a => Poly a -> Poly a -> Poly a
```

Complete the definition of (*) in your instance using timesP. Example:

```
1 P[1,2,3] * P[2,2] = P[2,6,10,6]
```

Proceed as follows:

i. Multiply the second polynomial with each coefficient $c_0, c_1, ...$ in the first polynomial separately.

```
P [1,2,3] * P [2,2]: 1 * P [2,2] = P [2,2],

2 * P [2,2] = P [4,4],

3 * P [2,2] = P [6,6]
```

ii. Shift the result of c_i i decimal places to the right.

```
1 | P [1,2,3] * P [2,2]: shift 0 $ 1 * P [2,2] = P [2,2],
shift 1 $ 2 * P [2,2] = P [0,4,4],
shift 2 $ 3 * P [2,2] = P [0,0,6,6]
```

iii. Calculate the sum of all intermediate results.

```
P [1,2,3] * P [2,2] = P [2,2] + P [0,4,4] + P [0,0,6,6] = P [2,6,10,6]
```

(g) Write a definition of negate for your instance. This function should return the negation of a polynomial. In other words, the result of negating all of its terms. For example: $3x^2 - x + 6 \equiv -(3x^2 - x + 6) \equiv -3x^2 + x - 6$ or negate (P [6,-1,3]) \equiv P [-6,1,-3]

```
Note

By defining (+) and negate we get (-) for free, without having to implement it.
```

- (h) Write a definition of abs :: a -> a for your instance which turns all coefficients to positive numbers.³ For example: abs (P [6,-1,3]) ≡ P [6,1,3]
- (i) Write a definition of signum :: Poly a -> Poly a for your instance. The "sign" of a polynomial $P = c_n x^{e_n} + \cdots + c_1 x^{e_1}$ ($c_n \neq 0$, if n > 1) shall be defined as:

$$signum(P) = \left\{ \begin{array}{ccc} +1 & , & c_n > 0 \\ 0 & , & c_n = 0 \\ -1 & , & c_n < 0 \end{array} \right.$$

Note

You may have to add more type class constraints to the context of your instance declarations.

Examples:

```
1 | signum $ P [3,-2,0,1] = P [1]
2 | signum $ P [3,-2,0,-1] = P [-1]
```

(j) Bonus (optional): Note that the Prelude documentation for signum says:

"The functions abs and signum should satisfy the law: abs x * signum x == x"

Can you give an alternative implementation of abs—possibly different to the one we implemented in the previous subtask—such that the law is satisfied?

Now that we have completed the Num instance for polynomials, we can stop using coefficient list syntax. The polynomial $x^2 + 5x + 3$ can now directly be written as

```
1 \mid x^2 + 5*x + 3
```

This is a composition of expressions of type Poly Int, using the overloaded operators of Num (Poly Int), next to value x (recall your definition in (a)) and the operator (^), which is also defined in terms of the Num instance:

```
1 | Prelude> :t (^)
2 | (^) :: (Num a, Integral b) => a -> b -> a
```

 $^{^3}$ This definition is far away from a mathematical *absolute value* function for polynomials which would have to be a mapping from polynomials to numbers of \mathbb{R} . However, it fits the given signature for **abs** and might be a reasonable and practical interpretation of what an **abs**-function for **Poly a** in Haskell might be associated with.
